All cancers harbor molecular alterations in their genomes. The transcriptional consequences of these somatic mutations have not yet been comprehensively explored in lung cancer. Here we present the first large scale RNA sequencing study of lung adenocarcinoma, demonstrating its power to identify somatic point mutations as well as transcriptional variants such as gene fusions, alternative splicing events, and expression outliers. Our results reveal the genetic basis of 200 lung adenocarcinomas in Koreans including deep characterization of 87 surgical specimens by transcriptome sequencing. We identified driver somatic mutations in cancer genes including *EGFR*, *KRAS*, *NRAS*, *BRAF*, *PIK3CA*, *MET*, and *CTNNB1*. Candidates for novel driver mutations were also identified in genes newly implicated in lung adenocarcinoma such as *LMTK2*, *ARIDIA*, *NOTCH2*, and *SMARCA4*. We found 45 fusion genes, eight of which were chimeric tyrosine kinases involving *ALK*, *RET*, *ROSI*, *FGFR2*, *AXL*, and *PDGFRA*. Among 17 recurrent alternative splicing events, we identified exon 14 skipping in the proto-oncogene *MET* as highly likely to be a cancer driver. The number of somatic mutations and expression outliers varied markedly between individual cancers and was strongly correlated with smoking history of patients. We identified genomic blocks within which gene expression levels were consistently increased or decreased that could be explained by copy number alterations in samples. We also found an association between lymph node metastasis and somatic mutations in *TP53*. These findings broaden our understanding of lung adenocarcinoma and may also lead to new diagnostic and therapeutic approaches.

[Supplemental material is available for this article.]

Lung cancer is one of the most common cancers in humans, as well as the leading cause of cancer-related death worldwide (Jemal et al. 2011). Although diagnosis at an early stage is increasing with the introduction of low-dose computerized tomography screening, lung cancer is still a devastating disease that has a very poor prognosis (Aberle et al. 2011). Lung cancer can be classified based on histopathologic findings, with adenocarcinoma being the most common type (Travis et al. 2005). Recently, deeper understanding of the major genetic alterations and signaling pathways involved has suggested a reclassification of lung adenocarcinoma based on underlying driver mutations. Cancer cells with these genetic

alterations have survival and growth advantages over cells without such changes (Haber and Settleman 2007). Currently, approximately 10 driver genes have been discovered in lung adenocarcinoma (Pao and Girard 2011). Clinical trials using new chemotherapeutic agents targeting such alterations have demonstrated remarkable improvements in patient outcome, for example gefitinib (Mok et al. 2009; Maemondo et al. 2010) and crizotinib (Kwak et al. 2010) for lung adenocarcinoma harboring *EGFR* mutations and *EML4-ALK* (Soda et al. 2007) fusion, respectively. More recently, not only point mutations but also tyrosine kinase gene fusions, such as *KIF5B-RET*, were identified as driver mutations (Ju et al. 2012). Nevertheless, we still do not know the molecular drivers of ~40% of lung adenocarcinomas (Pao and Girard 2011). Interestingly, the frequencies of some driver mutations have been shown to be significantly different between ethnic groups (Shigematsu and Gazdar 2006), and therefore comprehensive cancer genome studies in a range of human populations will help to find new molecular alterations that can be targeted in treatments of lung cancer.

Article published online before print. Article, supplemental material, and publication date are at <http://www.genome.org/cgi/doi/10.1101/gr.145144.112>. Freely available online through the *Genome Research* Open Access option.

In this study, we broadly surveyed genetic alterations in 200 fresh surgical specimens of lung adenocarcinoma in Koreans. Eighty-seven of these were analyzed by transcriptome sequencing combined with whole-exome ( $n = 76$ ) and transcriptome sequencing ( $n = 77$ ) for matched adjacent normal tissue samples. Transcriptome sequencing is a powerful method for detecting driver mutations in cancer, since not only somatic point mutations but also aberrant RNA variants such as fusion genes and alternative splicing can be examined. Though advances in genomic technologies have enabled genome-wide analyses of cancers, to our knowledge this is the first large-scale study of lung adenocarcinoma using RNA sequencing.

## Results

### Cancer samples analyzed in this study

We collected 200 fresh surgical specimens of primary lung adenocarcinoma from patients who underwent major lung resection (Supplemental Fig. 1). For each patient, we recorded diagnosis, gender, cancer stage, and smoking status (Supplemental Table 1). Among the 200 cancer patients, the proportions of females and never-smokers were 54.5% ( $n = 109$ ) and 58.0% ( $n = 116$ ), respectively. Of these, 87 cancer tissues whose driver mutations were not detected by screening tests (Sanger sequencing for *EGFR* and *KRAS* point mutations and fluorescence in situ hybridization [FISH] for *EML4-ALK* fusion) (Supplemental Table 1; Supplemental Fig. 1) were analyzed by transcriptome sequencing combined with whole-exome ( $n = 76$ ) and transcriptome ( $n = 77$ ) sequencing of matched normal lung tissue samples (Supplemental Table 2; Supplemental Material). All these sequencing experiments were done as described previously (Ju et al. 2011). We generated 14,038,673,860 paired-end 101-bp-long reads from RNA sequencing of 164 samples (87 cancer and 77 corresponding normal tissues). On average, the RNA sequencing throughputs were 9.77 and 7.38 Gbp for cancer and normal tissues, respectively. In the whole-exome sequencing of normal tissues, we obtained 32.96-fold read depth per tissue for regions targeted by the exome capture platform used in this study.

### Somatic point mutations

Using our transcriptome data, we identified 4607 somatic non-synonymous single nucleotide substitutions and 373 coding short-indel mutations (Supplemental Fig. 2; Supplemental Table 3). Whole-exome sequencing of two randomly selected cancer samples provided an estimate of 89.2% for the accuracy of our somatic mutation discovery (Supplemental Table 4). The median number of somatic mutations in each cancer sample was 25. Among a total of 87 samples, 45 carried driver mutations in well-known cancer genes in lung adenocarcinoma, such as *EGFR* ( $n = 22$ ; in-frame deletions of exon 19, L858R and G719A) and *KRAS* ( $n = 18$ ; G12C, G12V, G12D, G12S, G13C, and G13D) (Fig. 1; Supplemental Table 3). In addition to *EGFR* and *KRAS*, other known mutations were also detected in *NRAS* (Sequist et al. 2011) ( $n = 3$ ; Q61H, Q61L, Q61K), *PIK3CA* (Ding et al. 2008) ( $n = 2$ ; H1047R and E555K), and *BRAF* (Ding et al. 2008) ( $n = 1$ ; V600E), which have all been reported as driver mutations of lung cancer. In addition, two samples carried known activating mutations in well-known oncogenes confirmed in other cancers (D32G of *CTNNB1* [Chan et al. 1999], M1124D of *MET* [Schmidt et al. 1999]), suggesting those mutations are also able to induce lung adenocarcinoma. Overall,

47 specimens harbored known point driver mutations in seven cancer genes (*EGFR*, *KRAS*, *NRAS*, *PIK3CA*, *BRAF*, *CTNNB1*, and *MET*), which we here refer to as “canonical point driver mutations.” These mutations were mutually exclusive with one exception of 1 *EGFR* and *PIK3CA* double-mutant. In addition to these known driver mutations, we also identified a set of genes, which were frequently mutated or highly overexpressed in a subset of cancers. Of note, *TP53* was the most frequently mutated gene. *CDKN2A*, *RET*, *NOTCH2*, *SMARCA4*, *LMTK2*, *ARID1A*, and *MTOR* were also frequently altered and are also worthy of note, since the functions of these genes are likely to be related to tumorigenesis or cancer maintenance (Fig. 1). The pairwise mutual exclusion and concurrence analysis for these mutated genes is shown in Supplemental Table 5.

### Fusion gene analysis

One of the advantages of transcriptome sequencing over genome sequencing is that detection of transcriptional variants, such as fusion genes and alternative splicing, is feasible. Using the gene fusion program (GFP) introduced previously (Ju et al. 2012) and typical gene expression patterns, we identified 45 in-frame fusion transcripts from the 87 cancer tissues (Fig. 2; Table 1; Supplemental Fig. 3; Supplemental Table 6). We attempted to validate all of the fusion genes using PCR amplification of cDNA and Sanger sequencing (Supplemental Fig. 4; Supplemental Table 7). Among 43 fusion genes where PCR primer was available, 39 were successfully validated (Supplemental Table 7). Interestingly, the four invalidated fusion genes all included either a surfactant gene (i.e., *SFTPB* or *SFTPA2*) or *H19*, whose wild-type gene expression was extremely high (greater than  $\sim 2000$  RPKM) in the corresponding specimen. This indicates that the fusion transcript may have been artificially synthesized during sequencing library construction.

Of the fusion genes we identified, eight were chimeric tyrosine kinases which are highly likely to play an important role in cancer development. Cancer specimens carrying one of the tyrosine kinase fusions ( $n = 10$ ) did not harbor any of the canonical point driver mutations ( $P$ -value =  $2.12 \times 10^{-4}$ ) (Supplemental Table 8). Of these eight fusion genes, four have been reported previously (*EML4-ALK* [Soda et al. 2007], *KIF5B-RET* [Ju et al. 2012; Kohno et al. 2012; Lipson et al. 2012; Takeuchi et al. 2012], *CD74-ROS1* [Rikova et al. 2007; Takeuchi et al. 2012], and *SLC34A2-ROS1* [Rikova et al. 2007; Takeuchi et al. 2012]), and we refer to them here as “canonical transforming fusion genes.” The remaining four fusion genes were novel (*CCDC6-ROS1*, *FGFR2-CIT*, *AXL-MBIP*, and *SCAF11-PDGFR*) (Fig. 3A). Of these four novel fusion genes, *CCDC6-ROS1*, *FGFR2-CIT*, and *AXL-MBIP* carry protein tyrosine kinase domains and dimerization units (Alberti et al. 2003; Ju et al. 2012) (coiled-coil or leucine zipper domains), both of which are essential to activate chimeric tyrosine kinases. The *SCAF11-PDGFR* fusion is an example of promoter swapping (Kas et al. 1997). Because the cancer specimens harboring these four novel fusion genes did not carry any known driver mutations (neither canonical point driver mutations [ $n = 47$ ] nor canonical transforming fusion genes [ $n = 6$ ];  $P$ -value = 0.021) (Supplemental Table 8), they may play important roles in cancer transformation. Other fusion genes identified in this study, such as *MAP4K3-PRKCE*, *BCAS3-MAP3K3*, *ERBB2IP-MAST4*, and *APLP2-TNFSF11* may also have functional importance since the genes are serine-threonine kinases or involved in signaling pathways. The co-occurrence of 45 fusion genes with canonical point driver mutations is shown in Supplemental Table 6.

**Figure 1.** The transcriptional landscape and mutational profile of 87 lung adenocarcinomas. Each column characterizes the signature of cancer in one patient. Patients are classified into smokers and never-smokers. Each row represents a selected gene of interest, including known driver genes of lung adenocarcinoma, genes observed to be frequently mutated ( $\geq 3$  cancers), and protein kinase genes involved in fusion and exon-skipping (ES) events. Cells are colored to indicate discovery of somatic mutations (red), gene overexpression (blue), both (purple), and fusion and ES events (green) in cancer tissue. Patients with lymph node metastasis are indicated with "M" on the bottom row.

**Figure 2.** Graphical representation of 45 fusion genes identified from transcriptome sequencing of 87 lung adenocarcinomas. Protein kinase-containing fusion genes are indicated with red lines joining the two genomic loci, while other fusions are indicated by blue lines. The protein kinase genes and their fusion partners are labeled in red and green, respectively (outer layer).

### Alternative splicing

Alternative splicing is known to be related to the pathogenesis of colon cancer (Gardina et al. 2006). We assessed exon skipping events preferentially occurring in the cancer tissue using the transcriptome sequencing data. From a total of 87 tissues, we identified 17 recurrent exon skipping events, where a specific exon of a gene is not in full transcription in cancer (Supplemental Table 9). In particular, three cases of skipping of exon 14 in *MET* were interesting (Fig. 3B), since *MET* protein tyrosine kinase is a well-known oncogene and this event was reported in lung adenocarcinoma previously (Kong-Beltran et al. 2006). Although the number of specimens harboring *MET* exon-skipping ( $n = 3$ ) is not sufficient for statistical testing, these three cancer genomes did not carry any of the canonical point driver mutations ( $n = 47$ ) or the canonical transforming fusion genes ( $n = 6$ ) ( $P$ -value = 0.057), suggesting that this exon-skipping event may have an independent transforming effect in the cancer. In addition, three cancer specimens expressed a short form of *FBLN2*, skipping exon 9. Skipping of exon 9 of *FBLN2* is also worthy of note (Supplemental Fig. 5), since this gene was recently introduced as a tumor suppressor candidate in nasopharyngeal carcinoma (Law et al. 2012).

### Lung adenocarcinoma in smokers

We compared the transcriptional landscape of lung cancers between ever-smokers and never-smokers. There was a

significant difference in the number of point mutations between the two groups (Fig. 4A). On average, smokers had significantly more amino acid-altering single nucleotide and short-indeletion mutations (65.0 and 20.6 mutations per cancer tissue of smokers [ $n = 40$ ] and never-smokers [ $n = 33$ ], respectively;  $P$ -value = 0.0011). Interestingly, the amount of smoking (pack-years) was positively correlated with the number of somatic point mutations in the cancer genome ( $P$ -value = 0.01; Supplemental Fig. 6). We also identified differences in mutational spectrums. Cancer tissues from smokers showed similar mutational signatures to those identified previously (Pleasance et al. 2010) ( $C > A$  transversion, most frequent;  $T > G$  transversion, least frequent), whereas cancers from never-smokers did not.  $C > A$  transversion was more frequent in smokers ( $P$ -value =  $3.1 \times 10^{-6}$ ), while  $T > G$  transversion was more common in never-smokers ( $P$ -value =  $8.1 \times 10^{-14}$ ) (Fig. 4B). In addition, from the gene expression profiles (Supplemental Material; Supplemental Table 10; Data Access), we detected a total of 6719 cancer outlier genes (COGs), which were extremely highly expressed in a small number of cancer tissues (Supplemental Table 11). The number of COGs per cancer tissue varied markedly (Fig. 4C), ranging from 0 to 989. The lung adenocarcinomas of smokers carried significantly more COGs than those of never-smokers ( $P$ -value = 0.0078) (Fig. 4C,D; Supplemental Fig. 7). These findings demonstrate that lung adenocarcinoma in smokers harbors more somatic mutations and greater perturbation of gene expression levels.

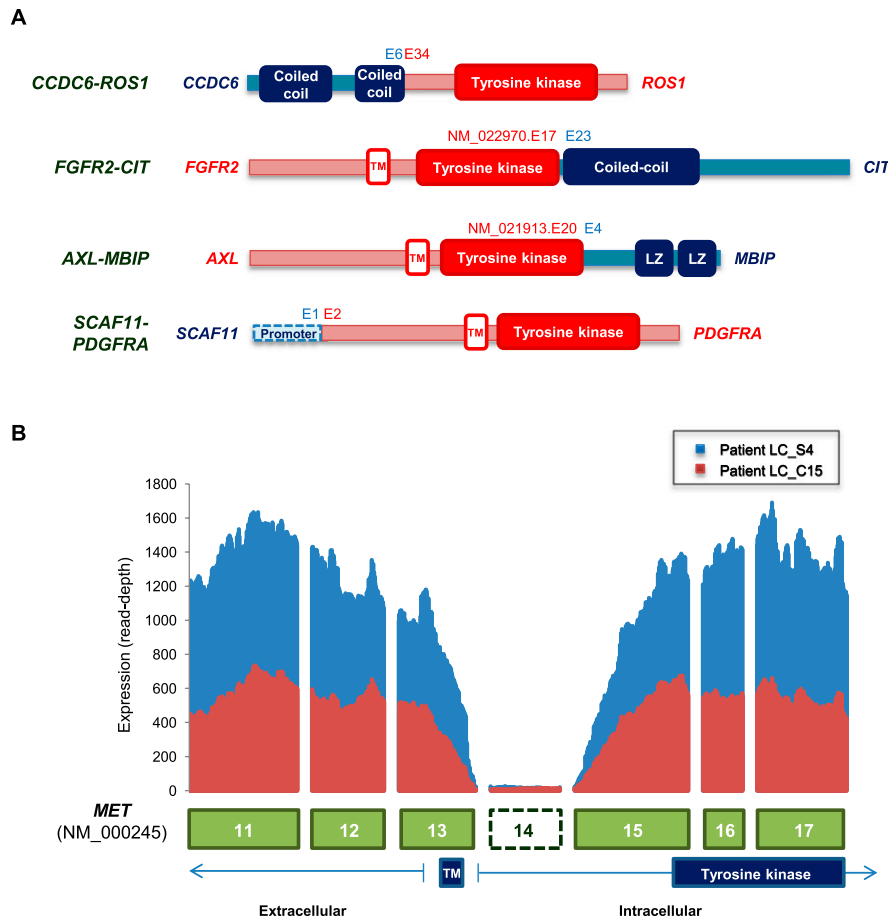

### Co-localization of over- and underexpressed genes

Next, we assessed the gene expression pattern of each specific cancer specimen relative to the general transcriptional landscape

**Table 1.** The list of 15 selected gene fusions identified from 87 lung adenocarcinomas

**Figure 3.** Fusion genes and alternative splicing events revealed by RNA sequencing. (A) Schematic figures of the domain structures of novel protein kinase fusion genes. (B) Exon 14 skipping in *MET* proto-oncogene demonstrated by read depth across gene model. (TM) *Trans*-membrane domain.

of all 87 cancer tissues. After identifying genes which were relatively overexpressed and underexpressed in each cancer, we interestingly observed that these sets were spatially grouped together in the genome (Fig. 5A; Supplemental Fig. 8). We defined those regions containing such groups as jointly regulated blocks (JRBs). The number of JRBs was highly variable among cancer tissues. In order to investigate the cause of these JRBs, we performed comparative genomic hybridization (CGH) array (Park et al. 2010) experiments on a subset of cancer samples ( $n = 9$ ). Interestingly, combined analyses between array results and JRBs showed that ~70% of JRBs can be explained by the copy number status of the cancer genome (Fig. 5A,B). Recent reports have also shown that cancer genomes harbor large hypo-methylated (and hyper-methylated) blocks (Wen et al. 2009; Hansen et al. 2011), suggesting the combined effect of somatic copy number alterations and DNA methylation patterns are likely to induce the diversity of gene expression profiles in cancer tissues.

We merged the JRBs identified from 87 lung adenocarcinoma samples. This clearly showed that the blocks are not randomly distributed in the genome (Fig. 5C). For example, gene expression is frequently increased on the short arm of chromosome 7, while expression is frequently decreased on the short arm of chromosome 3. These patterns correlate with frequent

copy number alterations of cancer genomes identified in previous studies (Weir et al. 2007; Job et al. 2010).

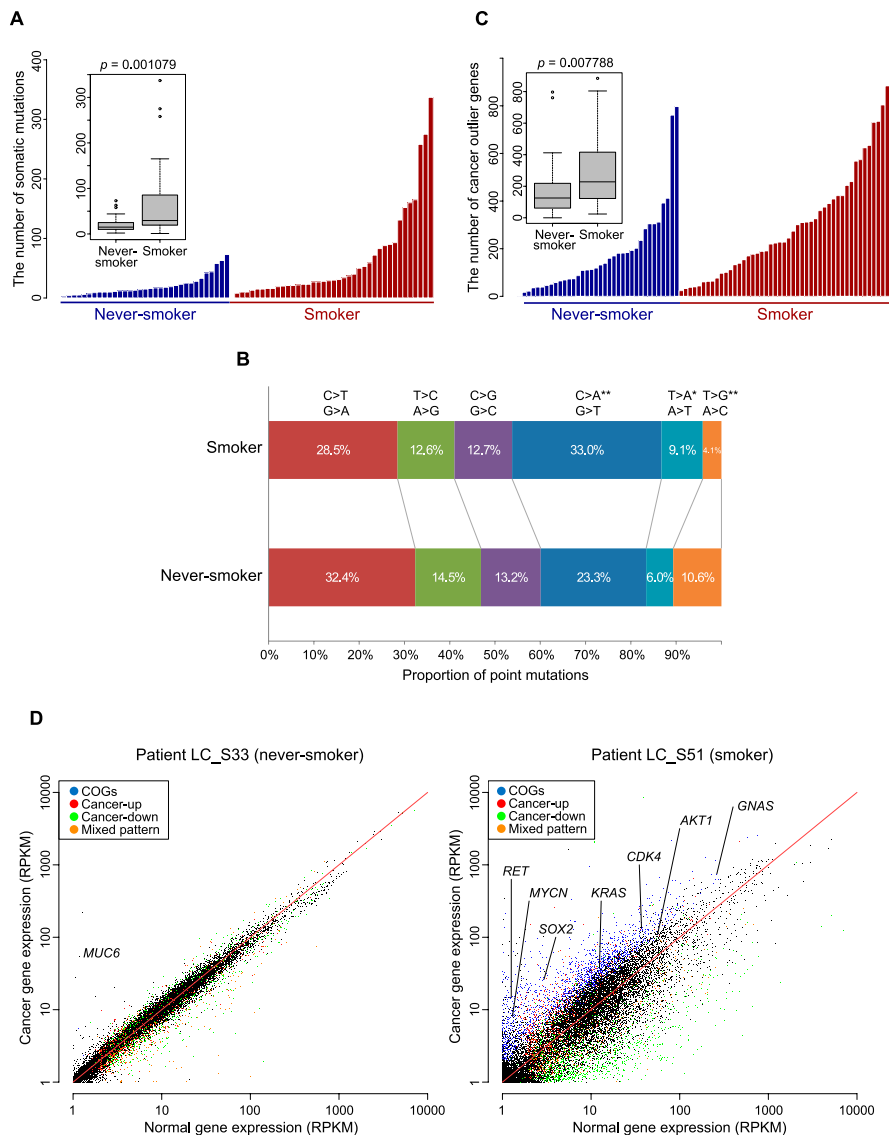

### Lymph node metastasis and *TP53* mutation

We investigated the correlation of somatic alterations with lymph node metastasis (information for lymph node metastasis is available in Supplemental Table 1). We divided the cancer samples into two groups: those with known or candidate driver mutations (canonical point driver mutations [ $n = 47$ ], canonical transforming fusion genes [ $n = 6$ ], novel tyrosine kinase fusion genes [ $n = 4$ ; *CCDC6-ROS1*, *FGFR2-CIT*, *AXL-MBIP*, *SCAF11-PDGFR4*], and *MET* exon 14 skipping [ $n = 3$ ]) and those without. We performed multivariate logistic regression for the presence or absence of lymph node metastasis including gender, age, cancer stage, and smoking status as factors. Cancers with known or candidate driver mutations did not show a higher rate of lymph node metastasis than those without ( $P$ -value = 0.15; multivariate logistic regression) (Supplemental Table 2). However, cancer patients harboring both a known or candidate driver mutation and *TP53* mutations showed significantly higher rates of lymph node metastasis ( $P$ -value = 0.017; multivariate logistic regression) (Supplemental Table 2). This implies that activated oncogenes and disrupted tumor suppressor genes such as *TP53* may together contribute to cancer metastasis. In addition to driver and *TP53* mutations, cancer

stage showed significant association with lymph node metastasis ( $P$ -value = 0.00018; multivariate logistic regression) (Supplemental Table 2).

### Summary of driver mutations in lung adenocarcinoma

We summarize the mutational profiles of the 200 lung adenocarcinomas in Figure 6, including the results from transcriptome sequencing and from screening tests (99 with *EGFR* mutations, six with *KRAS* mutations, and seven with *EML4-ALK* fusions). The frequencies of *EGFR* and *KRAS* mutations in Korean patients were 60.5% ( $n = 121$ ) and 12.0% ( $n = 24$ ). Overall, ~75.5% ( $n = 151/200$ ) of lung adenocarcinomas are considered to be driven by point mutations in the 200 patients. In addition to point mutations, we found 17 tissues with fusion protein tyrosine kinase genes (*ALK*, *RET*, *ROS1*, *FGFR2*, *AXL*, and *PDGFR4*; 10 from transcriptome sequencing and seven from FISH study), which comprises 8.5% of all samples. Three samples (1.5%) carried activating exon skipping of *MET* tyrosine kinase, suggesting that ~10% of lung adenocarcinoma drivers are transcriptional variants that can be best investigated through transcriptome sequencing. Although we could not identify canonical driver mutations in 26 cancer tissues, we suggest some specific aberrations of note for each individual tissue (Supplemental Table 13).

**Figure 4.** Mutational and transcriptional variation in cancer between never-smokers and smokers. (A) The number of somatic mutations (nonsynonymous single nucleotide and short-indel mutations) in the cancer tissue of each patient. Patients are classified into never-smokers and smokers, and further sorted by mutation count. (Inset) Box plot of somatic mutation counts for never-smokers and smokers. The two groups are significantly different ( $P = 0.001079$ ). (B) The proportion of the six possible nonsynonymous substitutions found within smokers and never-smokers. The two groups were significantly different with respect to transversions C > A and T > G (\*\*,  $P < 0.001$ ) and transversion T > A (\*,  $P < 0.01$ ). (C) The number of cancer-outlier genes (COGs; extremely high-expressed genes in a subset of cancer specimens; see Methods for details) in each cancer tissue. Patients are sorted as above. (Inset) Box plot showing that lung adenocarcinoma in smokers contains more cancer-outlier genes. (D) Gene expression within cancer tissues against average expression in normal tissue. Scatter plots for patients LC\_S33 (a never-smoker patient) and LC\_S51 (a smoker patient) are shown, providing an example of the variation in gene expression perturbation. Selected genes of interest are labeled. Genes were categorized as “Cancer-up” where generally overexpressed and “Cancer-down” where generally underexpressed in lung cancer compared with paired-normal tissue by hierarchical clustering (see Supplemental Material).

## Discussion

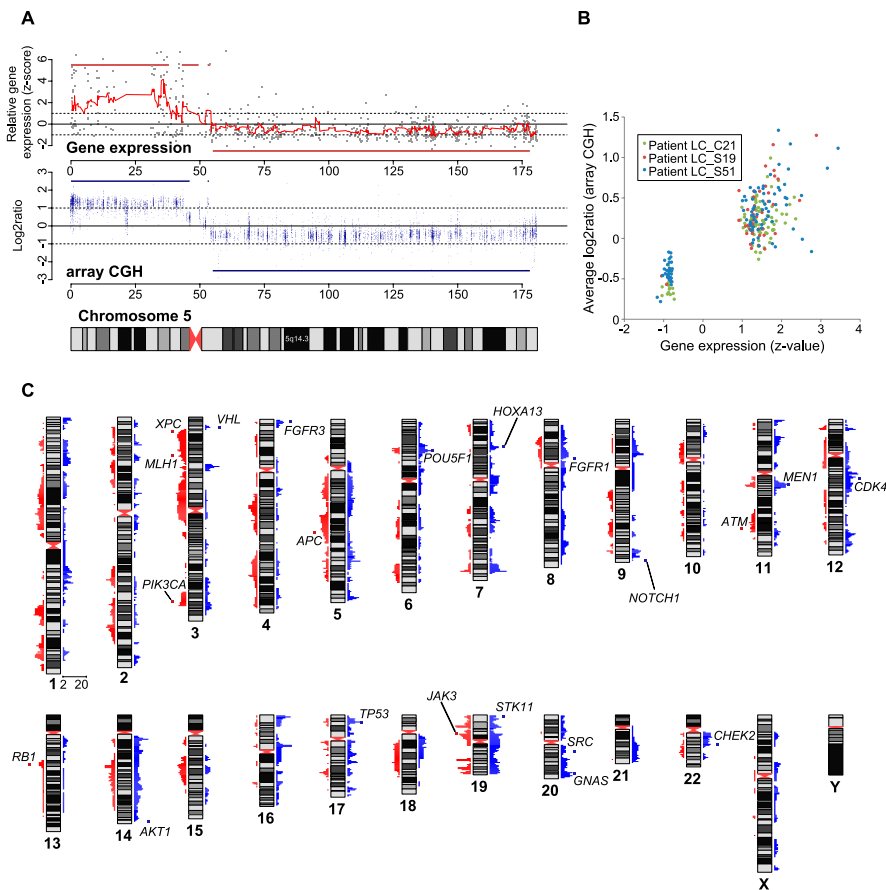

The landscape of lung cancer genomes has been widely investigated using genotyping microarray, sequencing of targeted cancer genes, CGH array, exome sequencing, and whole-genome sequencing (Ding et al. 2008; Beroukhi et al. 2010; Lee et al. 2010). These studies provided the large repertoire of known ge-

netic abnormalities in cancer genes (i.e., *EGFR* and *KRAS*), identified critical pathways (i.e., MAPK and PI3K pathway) for cancer transformation, and suggested putative druggable targets to develop more efficient treatments (Herbst et al. 2008). The transcriptional landscape of lung adenocarcinomas, however, has not yet been widely explored, although fusion genes, alternative splicing events, and gene expression outliers may have critical roles in cancer transformation. In addition, there are several unique characteristics of lung cancer in East Asians (Bell et al. 2008), including a large proportion of female patients, the predominance of adenocarcinoma over other types, and a high frequency of *EGFR* point mutations compared with Europeans. Investigation of such features may provide insights for the treatment or prevention of lung cancer in East Asians. Yet large-scale analysis of lung cancer genomes has not been performed in this ethnic group.

In this study, we have extensively analyzed the transcriptomes of 87 lung adenocarcinomas in Korean patients. Additional whole-exome and transcriptome sequencing for the adjacent paired-normal tissues was also performed to increase the specificity in identifying somatic mutations.

Transcriptome sequencing is a powerful tool to understand cancer because it captures a snapshot of diverse aspects of transformed cells. For instance, through whole-genome or whole-exome sequencing we can check for the presence of somatic mutations in cancer. However, transcriptome sequencing also provides a picture of dynamic consequences rather than just the mutations themselves. We can profile gene expression levels, gene fusions, and alternative splicing events simultaneously, all of which contribute to the proliferation of cancer cells. Moreover, RNA-seq is a very sensitive tool to identify point mutations. For example, six specimens which were negative for *EGFR* point mutations in the conventional screening test were discovered to harbor *EGFR* point mutations by transcriptome sequencing in this study. We believe that RNA sequencing is likely to outperform genome sequencing in de-

tection of cancer driver mutations, especially when tumor purity is relatively low. Genes with driver mutations in cancer cells are likely to be more highly expressed than in normal cells, therefore enhancing the signal-to-noise ratio in RNA-seq. For both approaches, it is important that systems are implemented which ensure the efficient collection and preservation of cancer tissues from clinic to bench.

**Figure 5.** JRBs identified from gene expression signatures. (A) Large JRBs observed on chromosome 5 in one cancer sample (patient LC\_S51) and its high correlation with CGH array results. (Top row) Relative expression levels of the genes on chromosome 5 (gray dots), their moving averages (red line), and detected JRBs (red horizontal bars). (Middle row) CGH array results for patient LC\_S51. Log<sub>2</sub> ratio of probes (blue dots) and identified copy number alterations (blue horizontal bars). (Bottom row) Karyogram of chromosome 5. (B) Correlation between JRBs and CGH array data for three cancer specimens. The x-axis represents the averaged Z-scores of JRB and the y-axis indicates the averaged CGH array log<sub>2</sub> ratios for the genomic area. (C) The genomic location of JRBs and number of cancer tissues involved. Increased- and decreased-expression JRBs are shown in blue and red bars, respectively.

Tumor heterogeneity is an important issue in cancer genome studies (Marusyk and Polyak 2010; Shah et al. 2012). Cancer tissue specimens with a low proportion of cancer cells require deeper read-depth when sequencing. We collected specimens from the center of tumors to attempt to obtain pure samples. The differences in numbers of somatic mutations per case as well as intrinsic variability in read allele frequency in RNA-seq (i.e., allele-specific expression and expression differences between cells) do not allow accurate estimation of tumor heterogeneity from cancer transcriptome sequencing data. Ignoring these issues, the distribution of read allele frequencies in cancer transcriptome sequencing for somatic point mutations suggests that the purity of the 87 specimens studied is ~80% on average (Supplemental Fig. 9). In addition, to increase the sensitivity in detection of somatic mutations, we performed deep RNA-sequencing (~10 Gb was sequenced for each cancer specimen) and applied relatively tolerant criteria for variant detection (i.e., read allele ratio should be ≥10% for SNV detection). However, somatic mutations from clones with lower frequencies may be unidentified in this study. One point worthy of note is that transcriptome sequencing can only detect somatic mutations from genes active in transcription. Somatic

mutations in nontranscribed genes cannot be detected. For example, a recent study reported that only ~36% of somatic mutations were expressed in breast cancers (Shah et al. 2012). However, this may be an advantage of transcriptome sequencing because somatic driver mutations must be transcribed to have a functional impact on the progression of cancer cells. Transcriptome sequencing enables us to focus on functionally active somatic mutations, thus providing functional insights into cancer genomes.

One of the aims of this project was to discover transforming fusion genes in lung adenocarcinomas. We estimated that studying 200 cancer tissues would provide 95.1% power to detect transforming fusion genes with a frequency of 1.5% in lung adenocarcinoma (Supplemental Material). By utilizing transcriptome sequencing technology, which is the most powerful method currently available to identify novel fusion genes (Maher et al. 2009), we found that *EML4-ALK*, *KIF5B-RET*, and *ROS1* fusions are the three major transforming fusion genes of adenocarcinoma in Koreans. We also identified novel gene fusions, including three protein tyrosine kinase fusions. These novel fusion genes appear to be rare events in lung adenocarcinomas, because we identified only a single case of each fusion gene among 200 samples. However, they may be good druggable targets, and more functional assessments of them are required in further studies.

From this study, we obtained evidence that expression levels of genes within a specific genomic region can be overexpressed (or underexpressed) together in JRBs, which are likely affected by differentially methylated regions (DMRs) or copy number alterations, which have been reported to be important in carcinogenesis (Beroukhi et al. 2010; Hansen et al. 2011).

Our CGH array analysis confirmed that genomic structural variations have a large-scale impact on the control of gene expression levels within such blocks. Future integrative studies, combining genomic structural variations, epigenomic changes, and gene expression levels of cancers are necessary to understand the fine-scale mechanisms that control gene expression in cancer cells.

Finally, we observed that the expression landscapes of the cancer tissues were extremely heterogeneous. As seen in the somatic point mutation and gene expression profile analyses, a subset of cancers harbored an extreme number of somatic point mutations and outlier genes. The pattern was unpredictable, but was not random and was associated with cigarette smoking. A recent study analyzing the impact of smoking on human normal lung tissues also supports our finding (Bosse et al. 2012).

In summary, we have comprehensively identified the genomic and transcriptional aberrations underlying lung adenocarcinoma in Koreans. The successful discovery of many aberrations in

**Figure 6.** A summary of the mutational profiles of 200 lung adenocarcinomas. Pie chart shows the distribution of driver mutations identified in 200 lung adenocarcinoma patients in this study.

cancer genes, such as somatic mutations, gene fusions, alternative splicing events, and cancer outliers, is most likely due to the strong power and comprehensive nature of whole-transcriptome sequencing. Our approach suggests a paradigm for large-scale deep transcriptome sequencing initiatives for a number of different cancer types. Our findings provide guidance for future translational studies correlating characteristics of cancer tissues and clinical features, such as drug response, recurrence, and survival.

## Methods

### RNA and exome sequencing

All protocols of this study were approved by the Institutional Review Board of Seoul National University Hospital (Approval # C-1111-102-387) and Seoul St. Mary's Hospital (Approval # KC11TISI0678).

All the cancer and adjacent paired-normal tissue specimens used in this study were acquired from surgical specimens. Cancer and normal tissue specimens were grossly dissected and preserved immediately in liquid nitrogen after surgery. For RNA-seq, we extracted RNA from tissue using RNAiso Plus (Takara Bio Inc.), followed by purification using RNeasy MinElute (Qiagen Inc.). RNA was assessed for quality and was quantified using an RNA 6000 Nano LabChip on a 2100 Bioanalyzer (Agilent Inc.). The RNA-seq libraries were prepared as previously described (Ju et al. 2011).

For exome sequencing of matched normal tissues (and cancer specimens LC\_C5 and LC\_C21 for validation purposes), genomic DNA was extracted from normal lung. Genomic DNA (3  $\mu$ g) from each sample was sheared and used for the construction of a paired-end sequencing library as described in the protocol provided by Illumina. Enrichment of exonic sequences was then performed for each library using the SureSelect Human All Exon 50Mb Kit (Agilent Inc.) following the manufacturer's instructions.

Libraries for RNA and exome sequencing were sequenced with Illumina TruSeq SBS Kit v3 on a HiSeq 2000 sequencer (Illumina Inc.) to obtain 100-bp paired-end reads. The image analysis and base calling were performed using the Illumina pipeline (v1.8) with default settings.

### Screening tests

Screening genetic tests were performed for identification of three well-known driver mutations in a subset of the 200 lung adenocarcinoma tissues as previously described: (1) Exon 18–21 of *EGFR* by PCR and Sanger sequencing (Lynch et al. 2004) ( $n = 164$ ); (2) Exon 2 of *KRAS* by PCR and Sanger sequencing (Eberhard et al. 2005) ( $n = 37$ ); (3) *EML4-ALK* fusion genes by FISH (Kwak et al. 2010) ( $n = 163$ ). The results of these studies are summarized in Supplemental Material and Supplemental Table 1.

### Smoking history

Of the 87 individuals whose cancer specimens were RNA sequenced, smoking history before diagnosis of lung cancer was provided by 83 (47 smokers, 36 never-smokers, and four unknowns). Information about the amount of smoking (pack-years) was available for 23 out of 47 smokers.

### Sequence analyses

RNA and exome sequencing reads were aligned to the NCBI human reference genome assembly (build 37.1) using GSNAP (Wu and Nacu 2010) with allowance for 5% mismatches. In the same manner, the RNA sequencing reads were also aligned to a cDNA set consisting of 161,250 mRNA sequences obtained from public databases (36,742 RefSeq, 73,671 UCSC, and 161,214 Ensembl) to decrease the false positives and false negatives in variant detection from RNA sequencing data (Ju et al. 2011, 2012). The expression levels for 36,742 RefSeq genes were measured by uniquely aligned RNA sequencing reads. For each gene, the number of reads aligned to it (raw read count) was normalized by RPKM (reads per kilobase per million mapped reads) (Mortazavi et al. 2008).

### Somatic single nucleotide and short-indel discovery

We first identified single nucleotide variations (SNVs) and short-indel variants in cancer using the transcriptome sequencing data. To minimize false positive calls generated by misalignment, we used variant calls commonly identified from both the genome and the mRNA alignment. SNVs were defined according to the following three conditions: (1) The number of uniquely mapped reads at the position should be  $\geq 3$ ; (2) the average base quality for the position should be  $\geq 20$ ; (3) the allele ratio at the position should be  $\geq 10\%$  for SNVs. Indels were called by the same procedure. Gene annotations for the variants were done using RefSeq genes. To identify somatic mutations, we removed SNVs and indels that were also identified in the normal tissue counterparts (76 whole-exome and 77 transcriptome sequencing). To remove potential germline variants that might not be filtered by this step, common germline SNPs that exist in normal human populations (variants identified from phase I of The 1000 Genomes Project [The 1000 Genomes Project Consortium 2010], variants with minor allele frequency  $>1\%$  from dbSNP 132 [Altshuler et al. 2010], and variants identified in normal Korean individuals [Ju et al. 2011]) were assumed to be unrelated to cancer transformation and were removed. These filtration steps might fail to remove some rare germline variants if the position was insufficiently covered in normal exome and transcriptome sequencing. However, we mostly focused on recurrent mutations in the later analysis, which are highly unlikely to be rare germline variants. Of note, among the 87 cancer specimens where RNA sequencing was performed, 11 did not have whole-exome sequencing of normal counterparts. Therefore, our lists of somatic mutations for the 11 cancer specimens are likely to include more rare germline variants than those

of the other specimens. We did not consider the 11 specimens in the statistical analysis of the number of somatic mutations and smoking history of lung cancer patients.

### Fusion gene detection

We detected in-frame fusion genes by utilizing the GFP software described in our previous report (Ju et al. 2012). Briefly, the method makes use of discordant read pairs, where two ends of a pair are mapped to different genes and exon-spanning reads across the exonic fusion breakpoint of chimeric transcripts. Additional filtration cascades (homology filter, fusion-spanning read filter, and the fusion point filter) were applied to remove false positives (Ju et al. 2012). In addition to GFP analysis, we also assessed read depth along each exon of tyrosine kinases (e.g., *ALK*, *RET*, and *ROS1*), since abrupt overexpression after fusion gene breakpoints is a hallmark of fusion for these genes (Supplemental Fig. 3; Ju et al. 2012; Lipson et al. 2012). We do not report intrachromosomal fusions between adjacent genes (<200 kb) because these are assumed to be due to read-through transcription and so do not originate in genomic rearrangement, e.g., translocation, inversion, or large deletion (Ju et al. 2012). Finally, off-frame fusion genes were removed.

### Alternative splicing

First, exon-skipping reads were extracted from the collection of sequencing reads for each cancer sample. The GSNAP alignment tool conveniently allows reads to be split into two segments and mapped to different exons when genomic positions of exons are provided to the program. We collected those spliced sequencing reads where nonadjacent exons of a gene were joined and defined them as exon-skipping sequencing reads. For candidate skipped exons supported by at least two exon-skipping reads, we obtained the expression levels for the candidate exon and its neighboring exons in terms of RPKM. Since the expression level for an exon is correlated with the expression level for the gene from which it derives, the expression of the exons was normalized by the expression level of the gene to which they belong. Next, the fold changes between the 5' neighboring and the 3' neighboring exons and the candidate exon were calculated and averaged. With an assumption of normal distribution, a Z-value for the fold change was obtained by considering all the fold changes calculated in the same manner in all the normal samples ( $n = 77$ ). If any of the normal averaged fold changes was <0.9, the candidate skipped exon was not further considered because dropped coverage was not specific to cancer.

### Differentially expressed gene (DEG) selection

We selected DEGs by clustering genes by expression levels. First, genes with either RPKM <1.0 or coefficient of variation (CV) <0.7 were excluded to remove genes noninformative for clustering. This resulted in a total of 3051 unique genes.  $\log_2$  transformation and additional row-wise and column-wise normalization was applied: Row-wise normalization was applied to each gene by subtracting the gene's median expression value from individual expression values. Similarly, column-wise normalization was applied to each sample by subtracting the sample's median expression value from individual expression values. This guarantees that row-wise and column-wise median expression values were both set to zero. Then, hierarchical clustering was done by Gene Cluster 3.0 with default parameters (de Hoon et al. 2004), correlation (uncentered), and complete linkage. A heatmap was drawn by R package function `heatmap.2` (<http://cran.r-project.org/web/packages/gplots/index>

html). Finally, we referred to the hierarchical tree generated by the clustering process and selected three types of DEGs (cancer-UP, cancer-DOWN, and mixed).

### Cancer outlier gene analysis

COG analysis was performed for 22,427 RefSeq genes across a total of 164 RNA-seq results with modified criteria suggested previously (Tomlins et al. 2005; MacDonald and Ghosh 2006). The analysis pipeline is as follows. (1) All the expression values are subtracted by their median, which sets the gene's median to zero (location normalization). (2) All the expression values are then divided by their median absolute deviation (MAD) (scale normalization). (3) Given a set of normalized expression values,  $q75 + 3 \times IQR$  is defined as an outlier cutoff where  $q75$  is the 75<sup>th</sup> percentile expression value and IQR (inter quartile range) is the absolute difference between the 25<sup>th</sup> and the 75<sup>th</sup> percentile expression values. An expression value is accepted as an outlier when its original RPKM is  $\geq 1.0$  and its normalized expression value exceeds the estimated outlier cutoff. (4) Genes showing an outlier pattern in any normal samples are excluded. (5) Finally, genes that exhibit an outlier pattern in at least one cancer sample are chosen as candidate COGs.

### Jointly regulated block (JRB) identification

To generate the gene expression signatures of each cancer sample, we calculated the ratio of gene expression levels in a cancer tissue to the average expression levels in 77 adjacent normal tissues. The gene set for analysis was formed from 36,742 transcripts in the RefSeq database, which yielded 22,427 genes after filtering out redundant entries.

To quantify relative expression among cancer samples, we compared the gene expression ratio of a gene (gene A) in the  $i^{\text{th}}$  cancer sample with the ratio in all 87 cancer tissues and calculated a normalized Z-score as follows:

$$\left( Z_{i,A} = \frac{\text{expression ratio}_{i,A} - \text{average expression ratio}_A}{SD_A} \right),$$

where SD is the standard deviation of expression ratios.

During this process, genes with low expression levels (maximum expression <3 RPKM) or genes with small variance in expressions (relative standard variation <0.1) were removed, since signal-to-noise ratio for these genes is not sufficient. This left 16,419 genes for further investigation.

Given a set of Z-scores, we calculated the moving average of 10 Z-scores by walking through the chromosomes. An increased expression JRB is defined as starting at a gene with a Z-score >1.5 and extending in both directions until a Z-score <0.5 is reached. Once its boundary is determined, the JRB must satisfy at least one of the three following criteria: (1) more than 40 genes within a block, (2) more than 20 genes in a block and an average Z-score >1.2, (3) an average Z-score >2.0. On the other hand, we applied slightly different conditions in discovering decreased expression JRBs to increase the sensitivity. A decreased expression JRB is defined as starting at a gene with a Z-score less than -1.0 and extending in both directions until a Z-score greater than -0.5 is reached. Then the JRB must satisfy at least one of the three following criteria: (1) more than 40 genes within a block, (2) more than 20 genes in a block with an average Z-score less than -0.8, (3) an average Z-score less than -1.0.

The comparison of JRBs and copy number alterations provided by CGH array was done by calculating the correlation ( $r^2$ ) between the averaged Z-scores of JRBs and the averaged  $\log_2$  ratio

values of probes within the same JRBs. CGH array analyses were performed using nine cancer samples (LC\_C7, LC\_C21, LC\_C25, LC\_C35, LC\_S19, LC\_S23, LC\_S39, LC\_S42, and LC\_S51) and their normal counterparts using a customized Agilent 180K CGH array platform (Park et al. 2010). CGH array experiments were conducted according to the manufacturer's instructions (Agilent Inc.). Briefly, genomic DNA from cancer and adjacent-normal specimens were labeled by Cy-5 and Cy-3 dye, respectively, and hybridized. Log<sub>2</sub> ratio was calculated by image analysis of CGH array using the CGH-105\_Jan09 protocol (Agilent Inc.) for background subtraction and normalization.

### Validation of fusion genes

Fusion genes were validated using PCR amplification of fusion gene breakpoints of chimeric cDNA and Sanger sequencing. The PCR reactions were 10 min at 95°C, 30 cycles of 30 sec at 95°C, 30 sec at 62°C and 30 sec at 72°C, and finally 10 min at 72°C. All the Sanger sequencing experiments were performed at Macrogen Inc. (<http://www.macrogen.com>). PCR and Sanger sequencing primers are shown in Supplemental Table 7.

### Statistical analyses

The differences in number of somatic mutations and COGs between smokers and never-smokers (Fig. 4A,C) were tested using Student's *t*-test.  $\chi^2$  tests were applied on the difference in mutation spectrums (Fig. 4B). Logistic regression analysis was performed to assess the relationship between somatic mutations (known or candidate driver mutations and *TP53* mutations) and lymph node metastasis using gender, age, cancer stage, and smoking status as covariates (Supplemental Table 12). Two-sided *P*-values were calculated for all these statistical tests.

### Mutual exclusion and concurrence analysis

We carried out pairwise mutual exclusion and concurrence analysis for genes that showed more than three mutations (including somatic point mutations, fusion genes, and skipped exons). For a given pair of mutated genes A and B, we recorded the number of samples in possible four categories (A mutated only, B mutated only, both A and B mutated, and neither). Then Fisher's exact test was performed to infer the mutual dependency between the two genes. Once two genes were determined to be mutually dependent on each other by the test, their mutual exclusion/concurrence was determined by calculating Pearson's correlation coefficient, *r* (mutual exclusion: *r* < 0 and concurrence: *r* > 0).

### Data access

Gene expression values for 87 lung adenocarcinomas and 77 adjacent normal tissues can be viewed at <http://gene.gmi.ac.kr> and at the NCBI Gene Expression Omnibus (GEO) (<http://www.ncbi.nlm.nih.gov/geo/>) under accession number GSE40419. Transcriptome and exome sequencing data are uploaded to the EBI European Nucleotide Archive (<http://www.ebi.ac.uk/ena/home>) under accession number ERP001058 (transcriptome sequencing) and ERP001575 (exome sequencing).

### Acknowledgments

We thank the anonymous lung adenocarcinoma patients who enrolled in this study. We also thank Whijae Roh at GMI-SNU for his help on the statistical analyses and Sung-Soo Park at W Corporation for his advice on constructing the website for browsing gene expression values. This work has been supported in part by

the Korean Ministry of Knowledge Economy (grant # 10037410 to J.-S.S.), and by the National Research Foundation (NRF) of Korea which is funded by the Korean Government (MEST) (Grant No. 2011-0016106 to Y.T.K. and a Global Ph.D. Fellowship to W.-C.L.).
